Received 17 September 1984

**ABSTRACT.** The results of measuring the intensity of coronal line 530.3 nm for the period 1977-1983 at the coronal stations of Lomnický Štit, Kislovodsk, Norikura and Sacramento Peak are compared. The method of comparison and determination of the formulas used to reduce the data of the mentioned coronal stations to the Lomnický Štit scale is described. The time stability of the compared data is analysed. An error in procedure was found for Lomnický Štit in the years 1979 and 1980. The reason why the error occurred is given, and the corrected values of the intensity are tabulated.

СРАВНЕНИЕ ШКАЛ КОРОНАЛЬНЫХ СТАНЦИЙ (эмиссионная линия 530.3 нм ; 1977 - 1983 ). В статье сравниены результаты определения интенсивности корональной линии 530.3 нм за период 1977 - 1983 гг на корональных станциях Ломницки Штит, Кисловодск, Норикура и Сакраменто Пик. Описан метод сравнения и определения трансформационных формул на шкалу станции Ломницки Штит. Оценена временная стабильность сравниваемых данных. У станции Ломницки Штит обнаружена систематическая ошибка за 1979 и 1980 гг. Определена причина ее возникновения и в таблице приведены исправленные данные.

POROVNANIE ŠKÁL KORONÁLNYCH STANÍC (emisná čiara 530,3 nm, 1977-1983). V práci sú porovnané výsledky merania intenzity koronálnej čiary 530,3 nm za obdobie 1977-1983 na koronálnych staniciach Lomnický Štit, Kišlovodsk, Nori-

kura a Sacramento Peak. Je opísaný spôsob porovnania a určenia transformačných funkcií na škálu stanice Lomnický Štít pre údaje z uvedených koronálnych staníc. Je hodnotená časová stabilita porovnávaných údajov. U stanice Lomnický Štít sa zistila chyba v postupe pri rokoch 1979 a 1980. Je opísaná príčina vzniku chyby a v tabuľke sú uvedené opravené hodnoty intenzít.

## 1. INTRODUCTION

The observations of the emission coronal line 530.3 nm, which are available (with a few gaps) since 1939, are an excellent measure of the changes in solar activity, as proved by Waldmeier, Trellis and others. The emission of this line originates in the Fe XIV ion and, therefore, accompanies high-energy phenomena in the solar corona, the substance of which is still not quite clear. Before the coming of the space age, these observations, together with observations of cosmic radiation, were the only source of information about high-temperature cosmic plasma. Beginning with 1947, therefore, a network of coronal stations was established, which were to observe the intensity of this line according to a uniform program, at intervals of  $5^{\circ}$  in position angle,  $40''$  above the photosphere and once daily.

Later, with the increasing amount of space experiments, many of these coronal stations gave up these systematic observations in the hope that they would be replaced by satellite observations. To-day (1984), however, the opinion prevails that this was a mistake and that these observations should be renewed with better resolution and using more accurate, automated measuring instruments.

The observations of a single station, particularly under European conditions, will never be sufficient to compile a continuous series of observations. For example, during the last 20 years a maximum of 80 observations a year were made at Lomnický Štít, whereas Sacramento Peak has recorded about 260. However, using just these observations does not solve the problem either, because they are not readily available (they are only published in graphical form in Solar Geophysical Data), the measurements are difficult to check and, particularly, because there is no certainty as to how long these data will be available at all; recently, the observation programs are frequently being changed and even long-term systematic measurements are sometimes being abandoned.

The network of coronal stations was organized to provide as continuous a series of observations as possible by supplementing the observations of one station by those of others. Unfortunately this objective was never completely achieved because, in spite of the long years of effort, the method of observation was never unified, which also applies to the photometry for the international service. The results from the various stations mostly differ quite considerably and, if they are to be used, a suitable method must be found of reducing them to a uniform scale and of creating a homogeneous series of intensities.

## 2. METHOD OF OBSERVATION

The initial data for comparing the observations made at various coronal stations are the averages on common observation days for the pair of stations being compared and the interval involved. One is immediately faced with the problem of a reference station.

The reference station should be capable of producing stable and reliably accurate results over a long period. However, there are no rules according to which one would be able to select a station with these properties at their best. Consequently, we decided to adopt our station as the reference station: Lomnický Štít. The reason for this is simple: each step of the observation procedure and photometry can be checked at our station, whereas this is not possible at other stations and the information they publish is insufficient.

The method of observation used is described in detail in the papers of Rybanský (1975, 1977); its basic steps will only be mentioned briefly here, and, in Section 3, each of the stations will be analysed in terms of the individual steps:

a/ A graph of the intensities (averages on common observation days) is plotted for both stations and for each year separately. If there are no conspicuous differences in the character of the observations (determined subjectively from the graph) the whole observation interval is reduced to a uniform scale.

b/ The displacement of the position angle scale of the station relative to the reference station is determined by cross-correlation.

c/ Using the values corrected for the position angle displacement, a graph is plotted of the functional dependence, a function is selected which would fit this dependence best, and the necessary parameters of the function are determined.

d/ The time stability of the reduction formula is analysed in terms of intensity and orientation (position angle) and a general characteristic of the comparison is presented.

## 3. RESULTS

As already mentioned, the results of the comparison will be given for each station (the reference symbol of the station which will be used hereinafter is given in parentheses following the name of the station) according to the items given in Section 2.

### LOMICKÝ ŠTÍT (LS):

This station was adopted as the reference station, so that items a/, b/ and c/ can be omitted. Only item d/ refers:

d/ The station comparison graphs indicate that, in 1979 and 1980, the intensities are systematically low at the other stations. The films for this period were checked, and it was found that the error is of an instrumental nature. At this time, the properties of the diffraction grating of the spectrograph deteriorated rapidly; its lifetime had probably come to an end. The met-

hod of abbreviated photometry used (Rybanský, 1971) requires the halfwidth of the measured line to vary only within narrow limits, and the line intensity is determined as the product of the measured central intensity of the line and the constant halfwidth. The deterioration of the properties of the grating led to an increase in the instrumental profile and lower intensities were obtained (in 1979 on the average by 0.903 x and in 1980 0.569 x). However, the correction cannot be made by multiplying the values in question by some coefficients, because the properties of the grating changed gradually. The spectrograms obtained in 1979 and 1980 were measured exactly, i.e. the central intensity and the halfwidth were determined. The corrected values are given in Table 1.

In 1981, the grating was changed and is, therefore, no longer a source of systematic errors.

KISLOVODSK (KI):

a/ The results of comparing the graphs indicate that the reduction formulas can be reduced to uniform scales in the following intervals: 1977-1980, 1981-1982 and 1983.

b/ As regards the first interval, the position angle should be corrected by  $-5^{\circ}$  in the range of  $90^{\circ}-175^{\circ}$ , in the second interval by  $-5^{\circ}$  all measurements, i.e. in the range of  $0^{\circ}-355^{\circ}$ , and in the third interval by  $-5^{\circ}$  in the range  $0^{\circ}-175^{\circ}$  and by  $-12.5^{\circ}$  in the range of  $180^{\circ}-355^{\circ}$ .

c/ Figure 1 indicates that the best fits for the period in question are: a broken line, a straight line and a broken line. Their parameters are given in Figure 1.

d/ The stability of the reduction formula is relatively small, mainly as regards the position angle and low intensities. The results show very good agreement in the second interval.

NORIKURA (NO):

a/ The reduction formulas are the same for the whole period in question.

b/ The position angle requires a correction of  $-2.5^{\circ}$  only in  $0^{\circ}-175^{\circ}$ .

c/ The best fits are straight lines, different for the eastern and western limb. The results and the line parameters are given in Figure 2.

d/ The stability of the reduction formula is good. The asymmetry of the data at the eastern and western limb persists. This asymmetry was also observed in the 1950's (Trellis, 1960).

SACRAMENTO PEAK (SP):

a/ The data for this station were obtained from the graphs published in Solar Geophysical Data (SGD). The calibration was corrected several times SGD-explanation of data reports, Altrock, 1984). The nature of the reduction is different for the interval 1977-1982 and 1983.

b/ The position angle has to be corrected by  $-1.5^{\circ}$  in the range of  $0^{\circ}-175^{\circ}$  for the first interval and by  $-1.0^{\circ}$  for the range of  $180^{\circ}-355^{\circ}$ . The 1983 correction for the whole range of position angles is  $-7.5^{\circ}$ .

c/ The best fit in the first interval is a broken line, in 1983 a straight line, as can be seen from Figs 3a, 3b and 3c.

d/ The stability of the reduction formula is high with the exception of

the change in 1983. The measurements at this station are carried out a height of 2' 24" above the photosphere as opposed to the 40" at stations LS and KI, and to 1' at NO. However, the reduced intensities agree well if one takes Rušin's (1973) gradient into account.

#### 4. CONCLUSION

The reduction formulas derived will be used to establish a homogeneous series of intensities of coronal line 530.3 nm in absolute units of the LS scale. This series will form the basis of various studies concerning the changes in the properties of coronal radiation during solar activity cycles.
